

Quick Check of Optical Module Light Receiving Sensitivity

Overview

A common test setup to evaluate Stressed Receiver Sensitivity involves measuring the Optical Modulation Amplitude (OMA) using a square wave, per the standard guidelines. Exceeding the BER value indicates signal degradation, rendering it unsuitable for data communication. The standards body governing the application sets this specified BER. Sensitivity is defined as how weak an input signal can get before the BER exceeds a specific number as defined by MSA standards. If this is too low, your module's laser might be dying. This tells you how much light. Optical fiber loss usually decreases with wavelength lengthening, 850nm loss is less, 900~1300nm loss becomes higher; and 1310nm becomes lower, 1550nm loss is the lowest, and loss above 1650nm tends to increase. So 850nm is the so-called short wavelength window, and 1310nm and 1550nm are long. This article compares practical, industry-standard ways to verify whether a transceiver is working — from the fastest visual checks to lab-grade measurements — so you can pick the right test for your skill level, equipment and required confidence.
